(Dated: August 28, 2008)

We study pattern formation during tensile deformation of confined viscoelastic layers. The use of a model system (PDMS with different degrees of crosslinking) allows us to go continuously from a viscous liquid to an elastic solid. We observe two distinct regimes of fingering instabilities: a regime called "elastic" with interfacial crack propagation where the fingering wavelength only scales with the film thickness, and a bulk regime called "viscoelastic" where the fingering instability shows a *Saffman-Taylor*-like behavior. We find good quantitative agreement with theory in both cases and present a reduced parameter describing the transition between the two regimes and allowing to predict the observed patterns over the whole range of viscoelastic properties.

**INTRODUCTION** – Good soft adhesives show viscous and elastic properties that allow on the one hand having a good molecular contact with the substrate and on the other hand a resistance to a certain stress level during debonding. The viscoelastic properties determine the debonding mechanisms when being detached from a rigid substrate, involving the formation of complex patterns as bulk fingering or interfacial crack propagation [1]. Pattern formation during tensile deformation of thin layers in confined geometries has also attracted much interest from a fundamental point of view. In the case of a purely viscous liquid confined between two plates being separated, air penetrating from the edges leads to the formation of bulk fingers. This fingering instability is well described by the classical *Saffman – Taylor* instability [2, 3, 4, 5, 6, 7], where a less viscous liquid pushes a more viscous liquid in a confined geometry. For a thin layer of a purely elastic material, undulations of an interfacial crack front have been observed experimentally and explained theoretically [8, 9, 10, 11]. Some studies have focused on complex or yield stress fluids [4, 5], elastic gels [12, 13], ferromagnetic fluids [14], pastes [15], or considered the role of the substrate [16]. The transition between a viscous liquid and a glassy material has been studied [17, 18].

However no systematic study of the pattern formation during deformation of a viscoelastic material focusing on the respective role of the liquid and elastic properties has been undertaken so far. We present here a system involving a specifically designed model soft material with tunable properties going continuously from a viscous liquid to an elastic solid. Studying the debonding mechanisms using a probe tack test on these materials allows for the

first time to explain the observed patterns quantitatively over the whole range of viscoelastic properties and to describe the transition between the two well known limits observed for a pure liquid or an elastic solid. Such a study helps for a better understanding of the instabilities observed in the viscoelastic regime of industrial applications. It is also of importance for any theoretical treatment aiming to bridge the gap between the different formalisms that apply to viscous liquids and elastic solids.

**MATERIALS AND METHODS** – As model system we use a weakly cross linked polymer, Poly(dimethylsiloxane) (PDMS). We chose the commercial product "*Sylgard® 184 Silicone Elastomer Kit*" purchased at *Dow Corning*. It consists of a silicone oil and a curing agent that is able to form cross links, i.e. chemical bonds between the polymer chains. The non cured silicone oil is a Newtonian liquid. Adding curing agent increases the number density of cross link points and the material becomes viscoelastic. The fully cured PDMS at 10% of curing agent is an elastic solid. This system thus represents an ideal model system providing a reproducible and easy way to go continuously from a viscous liquid to an elastic solid.

To determine the material's linear rheological properties, we perform oscillatory frequency sweep tests after curing in a plate-plate geometry. This gives access to the storage and loss moduli  $G'$  and  $G''$  that are measures for the material's elastic and viscous properties, respectively, as well as to the complex modulus  $G^* = \sqrt{G'^2 + G''^2}$ .

Figure 1 shows the results for different amounts of cross linker. The material with about 3% of cross linker is elastic, having a  $G'$  several orders of magnitude higher than

FIG. 1: The storage and loss moduli  $G'$  (full symbols) and  $G''$  (open symbols) as a function of the frequency  $\omega$  for different amounts of curing agent.

$G''$ ; adding about 1% of cross linker leads to a product in the viscoelastic regime close to the gel point.

We prepare polymeric films on microscope glass slides ( $10 \times 2.6 \times 0.2 \text{ cm}$ ) that are precleaned and coated with a primer (Dow Corning 1200 OS) to enhance the adherence of PDMS to the slide. We use applicators to deposit films of different thicknesses. The samples are cured in a desiccator at  $80^\circ \text{C}$  for five hours under vacuum. To determine the final thickness, we measure the film's weight and size. We validated this method by comparison with an optical technique using interference fringes.

We perform tensile deformation tests using a home built "probe tack" set up with good resolution and visualization capabilities [19]. It mainly consists of a flat circular steel probe that is brought into contact and debonded from a soft viscoelastic film with controlled speed, see figure 2. During the test, the probe displacement and the normal force on the probe are measured. We also visualize the debonding process from above with a camera mounted on a microscope to gain qualitative insight into the debonding mechanisms. The probe has a radius  $R = 3 \text{ mm}$  and is made of polished stainless steel.

**EXPERIMENTAL** – The parameters varied in our experiments, besides the viscoelastic properties, are the layer thickness  $b$  and the debonding speed  $v$ . Typical values are  $b = 50 - 500 \mu\text{m}$  and  $v = 1 - 200 \mu\text{m/s}$ . During a typical experiment, air penetrates from the edge of the confined layer. It can penetrate either in the bulk,

FIG. 3: Formation of air fingers in the elastic and viscoelastic case: interfacial crack propagation (a) and bulk deformation (b).

FIG. 4: *Left side, viscoelastic case*:  $\lambda$  depends on  $b$  and  $v$ .  $\square = 350 \mu\text{m}$ ,  $\blacksquare = 230 \mu\text{m}$ ,  $\circ = 120 \mu\text{m}$ ,  $\blacktriangle = 60 \mu\text{m}$ . *Right side, elastic case*:  $\lambda$  depends only on  $b$ .  $\square = 300 \mu\text{m}$ ,  $\circ = 130 \mu\text{m}$ ,  $\blacktriangle = 70 \mu\text{m}$ . Black lines are a guide for the eye.

followed by a strong deformation and the subsequent formation of thin "bridges" (fibrils) between the probe and the glass slide, or at the interface between the probe surface and the polymer film, leading to a fast debonding by interfacial crack propagation. In both cases, we observe the destabilization of the initially circular debonding line by undulations and the subsequent propagation of air fingers. We characterize the emerging patterns by determining the finger number  $n$  at the moment the first undulations are observable, see inset of figure 5, and calculate a wavelength  $\lambda = 2\pi R/n$ . Initially a destabilizing wavelength can be clearly defined, but as the time and debonding process go on, highly non-linear patterns are evolving, showing features like *side branching* and *tip splitting*, see figure 3. In the present study we restrict our interest to the analysis of the linear destabilization process at the onset.

**RESULTS AND DISCUSSION** – We characterize here in more detail the two cases of interfacial and bulk mechanisms introduced above. Although the patterns look quite similar in the top view pictures on figure 3 (a) and (b), two different mechanisms are at their origin.

In the case of the **viscoelastic regime** characterized by fibrillation and a bulk deformation mechanism, the

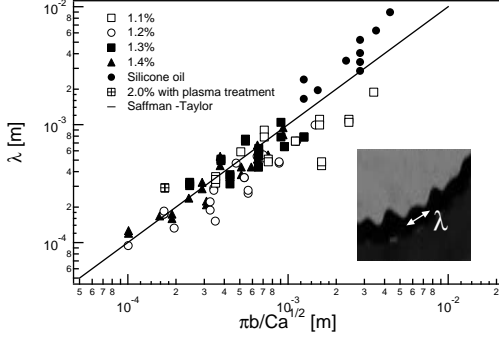

FIG. 5: In the viscoelastic case, the wavelength scales linearly with the thickness and is inversely proportional to the square root of the capillary number.

pattern formation is sensitive to both the initial film thickness and the debonding speed for a given material. As the wavelength decreases with the debonding speed and increases linearly with the initial film thickness (figure 4(a)), one can attempt to compare  $\lambda$  to the classical *Saffman - Taylor* (*ST*) or viscous fingering instability [2, 20] predicting by linear stability analysis

$$\lambda = \pi b / \sqrt{Ca} . \quad (1)$$

$Ca = U\eta/\sigma$  is the dimensionless capillary number comparing viscous to capillary forces,  $\eta$  the viscosity,  $\sigma = 20mN/m$  the surface tension between PDMS and air, and  $U$  denotes the radial velocity of the circular interface. Presuming an incompressible fluid and therefore volume conservation,  $U = Rv/2b$  for a Newtonian fluid. To adapt this prediction to the case of viscoelastic materials, we replace the Newtonian viscosity with a complex viscosity  $|\eta^*|$  defined as  $G^*/\omega$ .  $|\eta^*|$  depends on the frequency, estimated for each of our experiments following  $\omega = 2\pi U/b$ .

Figure 5 shows a good quantitative agreement between the *ST* prediction and our data, despite some scattering. The limit of a purely viscous liquid is represented by the dark full spots obtained for Newtonian silicone oils [21]. Surprisingly, the *ST* prediction holds going from the viscous limit up to highly non-Newtonian viscoelastic materials above the gel point.

The second case we investigated, the **elastic regime**, is characterized by interfacial crack propagation. The linear wavelength does not depend on the debonding speed over three decades, see figure 4(b). The dependence on the debonding speed is a quantitative criterion to decide which regime an experiment belongs to. Figure 6 shows that  $\lambda$  depends only on the initial film thickness  $b$  over three orders of magnitude of the elastic modulus ( $1kPa \lesssim G' \lesssim 0.5MPa$ ). These results are in qualitative agreement with theoretical predictions and with experimental observations in a slightly different geometry [8]. Linear stability analysis has also been done by

FIG. 6: In the case of interfacial crack propagation, the wavelength only scales with the thickness  $b$ . The solid line is a straight line fit to the data yielding  $\lambda = 2.3b$ .

Adda-Bedia and Mahadevan [9]. Considering the case of static peeling, they take into account the bending stiffness of the flexible cover plates used for the peeling tests and the finite film thickness. They calculate a critical confinement above which shear deformations are more beneficial for the system's energy than normal deformations, leading to undulations. The confinement parameter  $\alpha$  is defined as  $(D/Eb^3)^{1/3}$ ,  $D$  being the bending stiffness of the cover plate,  $E$  the film's elastic modulus and  $b$  the film thickness. The critical value  $\alpha_c \simeq 21$  is in good agreement with experiments by Ghatak *et al* who find  $\alpha_c \simeq 18$ . We compare our experiments to these results by considering the bending stiffness of our microscopic glass slides. With  $D \simeq 70Nm$  for a glass slide of  $b = 2mm$ , we find  $\alpha > 70$  for all our experiments, thus we place ourselves always in the regime of an unstable crack front. The critical wavelength calculated in [9]  $\lambda_c \simeq 3.4b$  scales only with the film thickness and is independent of all material parameters. Our result  $\lambda = 2.3b$  is in good quantitative agreement with theory. Deviations might be due to the fact that calculations are done for  $\alpha = \alpha_c$  whereas our experiments are placed far beyond the critical value.

A surprising result of our work is the very abrupt change in the debonding behavior: our experiments always fall into the elastic or viscoelastic regime without experiencing a transition regime. The appropriate parameter to describe the transition between interfacial and bulk mechanisms in the case of an elastic rubber has been proposed to be  $\mathcal{G}_c/Eb$  [13]. The critical energy release rate  $\mathcal{G}_c$  is a measure for the energy one has to provide to the system to make an interfacial crack move.  $Eb$  represents the elastic energy necessary to deform the bulk of a sample of thickness  $b$  with elastic modulus  $E$ . For a viscoelastic material,  $\mathcal{G}_c$  can be divided into a constant component  $\mathcal{G}_0$ , the threshold fracture energy, and a dissipation term depending on crack velocity. It has been proposed [22] that the dissipation term should be proportional to  $\tan \delta = G''/G'$ . Hence approximating  $\mathcal{G}_c \sim \mathcal{G}_0 \tan \delta$  and substituting into  $\mathcal{G}_c/Eb$  yields for soft

FIG. 7: Open symbols represent bulk deformation and black full symbols interfacial crack propagation. Experiments right at the transition can show both mechanisms due to fluctuations in the sample preparation.

viscoelastic layers a new parameter  $(\mathcal{G}_0 \tan \delta)/(G'b)$  depending only on the linear rheological properties and  $\mathcal{G}_0$  [23]. For cases where the energy cost to propagate a crack is high, bulk mechanisms are expected, while interfacial crack propagation should be observed when the elastic deformation of the layer requires high energy. This is well presented by plotting the parameter space spanned by  $(\mathcal{G}_0 \tan \delta)$  and  $(G'b)$ , see figure 7. Full symbols indicate interfacial, open symbols bulk mechanisms.

Following the theory it should be possible to switch between interfacial and bulk mechanism by changing  $\mathcal{G}_0$ . We performed an exemplary experiment replacing the steel probe ( $\mathcal{G}_0 \simeq 0.1 J/m^2$ ) by a glass surface previously subjected to plasma treatment, increasing  $\mathcal{G}_0 \simeq 15 J/m^2$  considerably. We estimated  $\mathcal{G}_0$  by measuring the work of adhesion for the fully cured PDMS performing a tack test at low debonding speed. We were indeed able to change the debonding mechanism from interfacial to bulk behavior for a sample with 2% of cross linker. This experiment is represented by the symbol  $\boxplus$  on figure 7. Furthermore, changing  $\mathcal{G}_0$  changes the wavelength which is now well described by the  $ST$  prediction, see  $\boxplus$  on figure 5.

**CONCLUSION** – We present in this Letter for the first time a systematic study of the transition between bulk deformation mechanisms and interfacial crack propagation during tensile tests on thin layers of viscoelastic materials with properties going from a viscous liquid to an elastic solid. In both cases, we characterize the emerging fingering patterns quantitatively following theoretical predictions. The transition we observe is very sharp without experiencing an intermediate regime. We propose a possible empiric parameter that allows to draw a mechanism map spanned by the parameters  $\mathcal{G}_0 \tan \delta$  and  $G'b$  separating nicely the different mechanisms and allowing therefore to predict the debonding behavior of our system.

We thank Mokhtar Adda-Bedia, Arezki Boudaoud and

Dominic Vella (LPS-ENS) for stimulating discussions and Guylaine Ducouret (PPMD-ESPCI) and Alexis Prevost (LPS-ENS) for help with the sample characterization.
